Abstract. In this paper, we propose the use of Information Theory as the basis for designing a fitness function for Boolean circuit design using Genetic Programming. Boolean functions are implemented by replicating binary multiplexers. Entropy-based measures, such as Mutual Information and Normalized Mutual Information are investigated as tools for similarity measures between the target and evolving circuit. Three fitness functions are built over a primitive one. We show that the landscape of Normalized Mutual Information is more amenable for being used as a fitness function than simple Mutual Information. The evolutionary synthesized circuits are compared to the known optimum size. A discussion of the potential of the Information-Theoretical approach is given.

Keywords: evolutionary algorithms, genetic programming, circuit synthesis, computer-aided design, evolvable hardware, information theory

1. Introduction

The implementation of Boolean functions using the minimum number of components is important for ASIC circuit designers and programmable devices since silicon surface on a chip is a limited resource. Classic graphical methods such as Karnaugh Maps become harder to use when the number of variables increases, and it becomes impossible to use for a relatively small number of variables. Tabular methods such as Quine-McCluskey, although amenable for digital computers, have been proved to need memory in the order of 3^n. Modern minimization CAD tools, like Espresso, and hybrid methods based on binary decision diagrams have proved very powerful for circuit design, therefore finding near optimal solutions to complex circuits. Such automated design tools

make use of *a priori* knowledge that human experts have extracted from the problem domain. Knowledge is stored and represented in the form of axioms and laws for immediate use. For example, knowledge of Boolean algebra is incorporated to Espresso in the form of three heuristics: reduce, expand, and redundant, aiming to construct the minimum set cover. In decision diagrams-based methods, rules for graph reduction preserving Boolean equivalence are used for minimization. For many design domains, human knowledge encoded in this form suffices to automate the design process. For some other areas such as logic circuit minimization, humans have not yet derived the whole set of rules that would allow to find the smallest circuit that implements an arbitrary Boolean function. Therefore, computation of the smallest circuit is achieved by searching for a solution in a combinatorial space spawned by operators of Boolean algebra.

As noted, the search space humans know (in some domains) is constructed by a deduction process, or repetitive application of the rules of the problem domain over an initial seed. But the search space could contain other elements not known to humans if it is created in some other way. Evolutionary computation methods build the search space in a bottom-up fashion by combining only some sampling elements (Thompson et al., 1999) (called individuals of the population). Hence, solutions found in this space challenge human designers since the deduction rules that lead to them are not common and, in many cases, such rules are in fact unknown.

Hybrid methods combining evolutionary computation algorithms and heuristics have proved very powerful. Nonetheless, purer forms of evolutionary algorithms deserve attention since the avoidance of human assistance is tantalizing.

In this article we use a pure form of Genetic Programming to synthesize logic circuits using binary multiplexer(s) ("mux" or "muxes"). That is, no knowledge is incorporated to the guiding search mechanism other than a fitness function based on entropy. We show that the Shannon expansion of a Boolean formula implementing a circuit is a sound basis for our evolutionary method. We also review several possibilities from information theory domain useful to fitness function design. The conclusions drawn here are applicable to any entropy-based fitness function for Boolean circuit design, regardless of the evolutionary technique in use.

The organization of this paper is the following: In Section 2, we describe some previous related work from both hybrid and pure areas. Section 3 provides the detailed description of the problem that we wish to solve. Section 4 provides the mathematical foundations for justifying the use of multiplexers as universal logic elements. Some basic

concepts of information theory and genetic programming are provided in Sections 5 and 6, respectively. The use of entropy for circuit design is discussed in Section 7. With these ideas in mind, we introduce fitness functions for evolutionary circuit design in Section 8. A set of experiments illustrating the design of logic circuits is described in Section 9. In Section 10, we provide some final remarks and our conclusions and, finally, in Section 11, we briefly discuss some possible paths for future research.

2. Previous Work

Most of the previous work in this domain has been done using Genetic Algorithms (GAs). Genetic Programming (Koza, 1992) is also included in this review, since this technique is really an extension of GAs in which a tree-based representation is used instead of the traditional linear binary chromosome adopted with GAs.

Louis (1993) introduced the use of GAs for the design of combinational circuits, and the use of a matrix array inside of which a circuit is evolved. A layer or stage of his circuits was constrained to get its inputs only from the previous stage. Thus, he defined a new operator called *masked crossover* that exploits information unused by standard genetic operators over the matrix representation. After Louis, several authors followed his representation, for example, Miller et al. (1998) also evolved logic circuits in a matrix but the position of the circuit output is also considered a variable. In their approach, Miller et al. (1998) encode a set of complex Boolean expressions instead of simple gate functions aiming to design more complex circuits given the set of more powerful primitives. In principle, the approach is sound but, unfortunately, its main drawback is its lack of flexibility to handle a large number of inputs. Miller et al. (2000; 2000a), Louis and Johnson (1997), and Islas et al. (2003) studied the combination of GAs with Case-Based Reasoning tools that incorporate and preserve knowledge about the problem domain.

Our own previous work using GAs for circuit design (Coello Coello et al., 1996; Coello Coello et al., 1997; Coello Coello et al., 2000; Coello Coello et al., 2001), shows successful results when small circuits are evolved inside the previously mentioned matrix representation. From our research using this sort of encoding, we concluded that the matrix causes a strong representation bias since some inputs and gates are favored by the genetic operators in a probabilistic sense. In an attempt to deal with such a biased representation, in more recent work, we proposed another approach based on genetic programming and multi-

plexers that seems to have a more neutral representation (Hernández Aguirre et al., 1999; Hernández Aguirre et al., 2000; Hernández Aguirre et al., 2000b).

Genetic programming (GP) is a natural alternative to genetic algorithms for circuit synthesis since its main goal is *program construction*, rather than vector optimization of the latter. Therefore, for GP, constructing a program is similar to constructing a circuit, with either domain being defined by its own set of terminals and functional symbols. Koza (1992) has used Genetic Programming to design combinational circuits, but his emphasis has been in the generation of functional circuits (in symbolic form) rather than their optimization. Dill et al. (1997) used GP to produce logic equations from partial information, covering up to 98.4% of the target function. Iba et al. (1997), have studied circuit synthesis at gate-level on FPGAs, concluding that intrinsic (on chip) evolution is harder than extrinsic (as our approach), because of the fine grained architecture of the FPGA. Note however, that we have showed that it is in fact possible for evolutionary algorithms to learn Boolean functions if we correctly estimate the so-called Vapnik-Chervonenkis dimension of our design tool (Hernández Aguirre et al., 2000a; Hernández Aguirre et al., 2001).

To establish the niche of this paper we should consider the two main approaches to Boolean function synthesis described in Section 1: pure methods, and hybrid methods. Pure methods are extended with procedures to cope with the poor scalability of evolutionary algorithms. Kalganova (2000) proposed a two-way strategy called "bidirectional incremental evolution", in which circuits are evolved in top-down and bottom-up fashion. Vassilev et al. (2000) proposed the use of predefined circuit blocks which can improve both the convergence speed and the quality of the solutions. Although these results are promising, a big problem remaining is defining what a good block is for the problem in turn. Recently, Torresen (2002) proposed a scalable alternative with limited success called "increased complexity evolution". Here, training vectors are partitioned, or the training set is partitioned, solving a problem in a divide and conquer fashion.

Hybrid methods have had more success, particularly binary decision diagram based methods. Droste (1997) used GP and two heuristics: deletion and merging rules, to reduce directed acyclic graphs. His approach solved the 20-multiplexer problem for the first time ever. Another important hybrid method has been developed by Drechsler et al. (1995; 1996; 1998). This GP system uses directed acyclic graphs for representing decision diagrams. Two heuristics that are representative of Dreschler's work are: sifting and inversion.

Claude Shannon suggested the use of information entropy as a measure of the amount of information contained within a message (Shannon, 1948). Thus, entropy tells us there is a limit in the amount of information that can be removed from a random process without information loss. For example, music can be (losslessly) compressed and reduced up to its entropy limit. Further reduction is only possible at the expense of information loss (Weaver and Shannon, 1949). In a few words, entropy is a measure of disorder and it constitutes the basis of Information Theory.

The ID3 algorithm for the construction of classifiers (based on decision trees) probably is the best known classification algorithm among computer scientists that relies on entropy measures (Quinlan, 1983). For ID3, an attribute is more important for concept classification if it provides greater "information gain" than the others.

Information Theory (IT) was early used by Hartmann et al. (1982) to convert decision tables into decision trees. Boolean function minimization through IT techniques has been approached by several authors (Kabakcioglu et al., 1990; Lloris et al., 1993). Some work related to the proposal presented in this article can be found in Luba et al. (2000; 2000a), whom address the synthesis of logic functions using a genetic algorithm and a fitness function based on conditional entropy. Their system (called *EvoDesign*) works in two phases: first, the search space is partitioned into subspaces via Shannon expansions of the initial function. Then the GA is started in the second phase. The authors claim that the partition of the space using entropy measures is the basis for their success. In their domain, a fitness function based on Mutual Information apparently worked well. Note however, that in our case such an approach did not produce good results. Conditional entropy has also been used by Cheushev et al. (2001) in top-down circuit minimization methods. In fact, the formal result of Cheushev et al. (2001) indicates that a Boolean function can be synthesized by using entropy measures, thus, providing a sound ground for our approach.

We aim to explore the use of entropy-based fitness functions in a pure GP framework. Since no other knowledge than entropy will be used in the fitness function, only limited size circuits can be tested. However, as noted before, the conclusions we draw are applicable to any evolutionary system for Boolean function synthesis based on entropy measures.

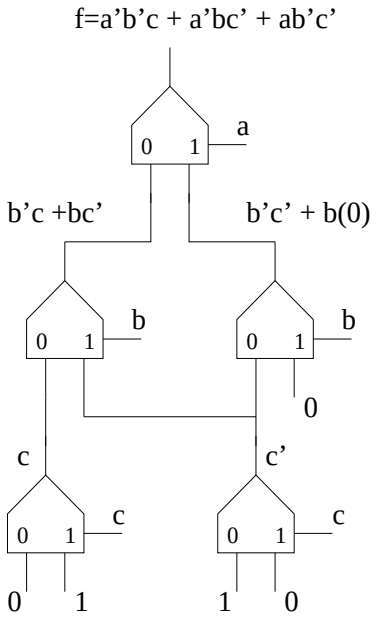

Figure 1. Shannon expansion implemented with binary multiplexers.

3. Problem Statement

For the purposes of this article, let us consider a target Boolean function T specified by its truth table. The problem of interest to us is the design of the smallest possible logic circuit, with the minimum number of binary multiplexers (described in Section 4), that implements the target function. The multiplexer is the only functional unit replicated, each one being controlled by a variable of the target function. Note that only 1s and 0s are fed into the multiplexers (the analog of the Shannon's expansion shown in Figure 1). This strategy allows the implementation of the synthesized circuits by means of pass transistor logic (Scholl et. al., 2000). The design metric driving the implementation is the number of components. Therefore, the best among a set of circuits with the same functionality is the one with the lowest number of components. Our goal is to find 100% functional circuits, specifying components and connections, instead of a symbolic representation of it. Thus, the approach of this paper could be classified as "gate-level synthesis".

Since the number of circuit components is unknown for most circuits, the use of an stochastic method such as Genetic Programming seems appropriate. Also, the tree-like structure of the circuits makes Genetic Programming the most appropriate evolutionary technique.

4. Multiplexers as Universal Logic Elements

The use of binary muxes is a sound approach to circuit synthesis since they can form a basis for Boolean functions. That is, muxes are "universal generators".

A binary multiplexer is a logic circuit with two inputs a and b, one output f, and one control signal s, logically related as follows:

$$f = as + bs' \tag{1}$$

In other words, the output is the value a when the selector is "high", and b when the selector is "low".

The Shannon expansion is the representation of a Boolean function through the residues of a Boolean function.

Definition 1. Residue of a Boolean function: The residue of a Boolean function $f(x_1, x_2, \ldots, x_n)$ with respect to a variable x_j is the value of the function for a specific value of x_j. It is denoted by f_{x_j}, for $x_j = 1$ and by $f_{\bar{x}_j}$ for $x_j = 0$. The Shannon expansion in terms of residues of the function is,

$$f = \bar{x}_j f|_{\bar{x}_j} + x_j f|_{x_j} \tag{2}$$

For mapping Boolean expansions into circuits using binary multiplexers, the variable x_j in Equation 2 takes the place of the control variable s in Equation 1. For the sake of an example consider the function $f(a, b, c) = a'b'c + a'bc' + ab'c'$.

The residue of the expansion over the variable a is:

$$\begin{aligned} f(a, b, c) &= a' f|_{a=0} + a f|_{a=1} \\ &= a' \cdot (b'c + bc') + a \cdot (b'c') \end{aligned}$$

The factor $b'c + bc'$ must be taken by the mux when the selector a is "low", and $b'c'$ when a is "high". These factors could also be expanded in the same way. The expansion of the first factor over the variable b is:

$$\begin{aligned} b'c + bc' &= b'(b'c + bc')|_{b=0} + b(b'c + bc')|_{b=1} \\ &= b' \cdot c + b \cdot c' \end{aligned}$$

And the expansion of the second factor over b is:

$$\begin{aligned} b'c' &= b'(b'c')|_{b=0} + b(b'c')|_{b=1} \\ &= b' \cdot c' + b \cdot 0 \end{aligned}$$

Since in our approach the only valid inputs to the muxes are "0" and "1", the variable "c" has to be fed to the circuit through a mux. This is done by the two muxes at the bottom of the "tree". The circuit implementing the function of our example is shown in Figure 1.

5. Basic Concepts of Information Theory

Uncertainty and its measure provide the basis for developing ideas about Information Theory (Cover and Thomas, 1991). The most commonly used measure of information is Shannon's entropy.

Definition 2. Entropy: The average information supplied by a set of k symbols whose probabilities are given by $\{p_1, p_2, \ldots, p_k\}$, can be expressed as,

$$H(p_1, p_2, \ldots, p_k) = -\sum_{s=1}^{k} p_k log_2 p_k \tag{3}$$

The information shared between a transmitter and a receiver at either end of a communication channel is estimated by its Mutual Information,

$$MI(T;R) = H(T) + H(R) - H(T,R) = H(T) - H(T|R) \tag{4}$$

The conditional entropy $H(T|R)$ can be calculated through the joint probability, as follows:

$$H(T|R) = -\sum_{i=1}^{n}\sum_{j=1}^{n} p(t_i r_j) log_2 \frac{p(t_i r_j)}{p(r_j)} \tag{5}$$

An alternative expression of mutual information is

$$MI(T;R) = \sum_{t\in T}\sum_{r\in R} p(t,r) log_2 \frac{p(t,r)}{p(t)p(r)} \tag{6}$$

Mutual information, Equation 4, is the difference between the marginal entropies $H(T) + H(R)$, and the joint entropy $H(T,R)$.

Table I. Function $f = a'b'c + a'bc' + ab'c'$ used to compute MI(f;c).

a	b	c	f=a'b'c+a'bc'+ab'c'
0	0	0	0
0	0	1	1
0	1	0	1
0	1	1	0
1	0	0	1
1	0	1	0
1	1	0	0
1	1	1	0

We can explain it as a measure of the amount of information one random variable contains about another random variable, thus it is the reduction in the uncertainty of one random variable due to the knowledge of the other (Cover and Thomas, 1991).

Mutual information is not an invariant measure between random variables because it contains the marginal entropies. Normalized Mutual Information is a better measure of the "prediction" that one variable can do about the other (Studholme et al., 1999):

$$NMI(T;R) = \frac{H(T) + H(R)}{H(T,R)} \tag{7}$$

The joint entropy $H(T,R)$ is calculated as follows:

$$H(T,R) = -\sum_{t \in T} \sum_{r \in R} p(t,r) log_2 p(t,r) \tag{8}$$

Normalized MI has been used in image registration with great success (Maes et al., 1997).

Example: We illustrate these concepts by computing the Mutual Information between two Boolean vectors f and c, shown in Table I. Variable c is an argument of the Boolean function $f(a,b,c) = a'b'c + a'bc' + ab'c'$.

We wish to estimate the description the variable c can do about variable f, that is, $MI(f;c)$.

We use Equations 4 and 5 to calculate $MI(f;c)$. Thus, we need the entropy $H(f)$ and the conditional entropy $H(f|c)$.

Entropy requires the discrete probabilities $p(F=0)$ and $p(F=1)$ which we find by counting their occurrences

$$H(f) = -(\frac{5}{8}log_2\frac{5}{8} + \frac{3}{8}log_2\frac{3}{8}) = 0.9544$$

The conditional entropy, Equation 5, uses the joint probability $p(f_i, c_j)$, which can be estimated through conditional probability, as follows: $p(f,c) = p(f)p(c|f)$. Since either vector f and c is made of two symbols, the discrete joint distribution has four entries. This is:

$$\begin{aligned}
p(f=0,c=0) &= p(f=0)p(c=0|f=0) = \frac{5}{8}\times\frac{2}{5} = 0.25\\
p(f=0,c=1) &= p(f=0)p(c=1|f=0) = \frac{5}{8}\times\frac{3}{5} = 0.375\\
p(f=1,c=0) &= p(f=1)p(c=0|f=1) = \frac{3}{8}\times\frac{2}{3} = 0.25\\
p(f=1,c=1) &= p(f=1)p(c=1|f=1) = \frac{3}{8}\times\frac{1}{3} = 0.25
\end{aligned}$$

Now, we can compute the conditional entropy by using Equation 5. The double summation produces four terms:

$$\begin{aligned}
H(f|c) &= -(\frac{1}{4}log_2\frac{1}{2} + \frac{3}{8}log_2\frac{3}{4} + \frac{1}{4}log_2\frac{1}{2} + \frac{1}{8}log_2\frac{1}{4})\\
H(f|c) &= 0.9056
\end{aligned}$$

Therefore, $MI(f;c) = H(f) - H(f|c) = 0.9544 - 0.9056 = 0.0488$. In fact, for the three arguments of the example function we get $MI(f;a) = MI(f;b) = MI(f;c)$. The normalized mutual information between either argument and the Boolean function is $NMI(f;a) = NMI(f;b) = NMI(f;c) = 1.0256$. Although no function argument seems to carry more information about the function f, we show later that the landscape of NMI contains a region implying information sharing. This region is hard to find on the MI landscape.

6. Genetic Programming Concepts

Genetic Programming is a variation of the genetic algorithm in which a tree-based representation is adopted. Its main aim is to solve automatic programming problems and symbolic regression problems (Koza,

1992). Problems such as the exponential growth of the search space even for some very specific problem domains, and the representation or encoding of computational structures of the objective language, remained unsolved for several years. John R. Koza (1992), used genetic algorithms to tackle the search space problem, and S-expressions which are naturally encoded as trees, to represent programs. The evolutionary operations applied over trees always produce valid trees and, therefore, syntactically correct programs. One of the earliest genetic programming systems ran in LISP, as to take advantage of the native parser provided by this programming language. Thus, the language interpreter "runs" the evolutionary algorithm, and at the same time is the evaluator of the S-expressions produced by the evolutionary algorithm.

Genetic Programming evolves functions encoded as trees. We should see a tree as the abstract semantic view of a program, that is, a parse tree. Therefore, nodes and leaves of the tree represent non-terminal and terminal grammar elements of the objective language. Furthermore, genetic programming has to be initialized with a set of operators and functions that work as a basis for the evolutionary synthesis of programs. For example,

- Arithmetic operations (e.g., $+, -, \times, \div$)
- Mathematical functions (e.g.,sine, cosine, log, exp)
- Boolean operations (e.g., AND, OR, NOT)
- Conditionals (IF-THEN-ELSE)
- Iterators (DO-UNTIL)

These are operators and functions commonly adopted in genetic programming. For the evolution of logic circuits we define a pertinent set of grammar elements (note the relationship with Figure 1):

- Terminals= $\{0, 1\}$
- Non-terminals= {a multiplexer}

Therefore, a circuit is represented as a tree using binary multiplexers as node functions, and 0s and 1s for the leaves. An illustration of this kind of tree is shown in Figure 2 (the circuit was derived using the technique described in this article). The circuit is 100% functionally equivalent to the one derived by Shannon expansions in Figure 1. Note that the circuits are also structurally similar but the muxes are controlled by different variables.

The main body of the standard Genetic Programming algorithm is the following:

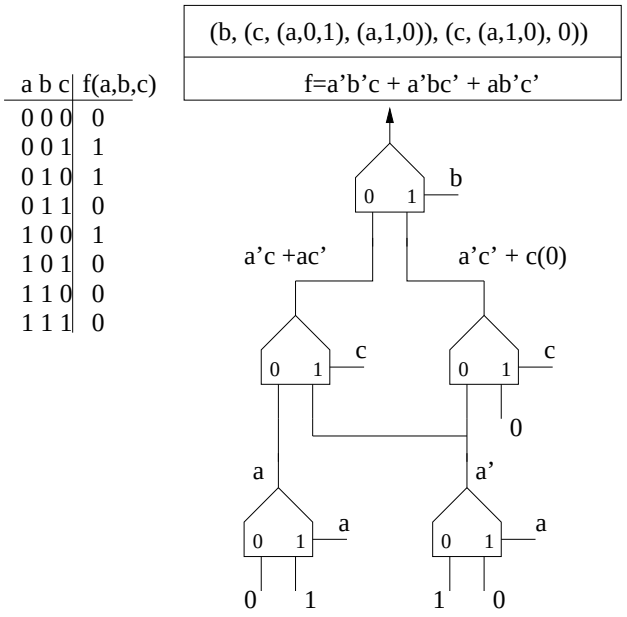

Figure 2. Logic function specification, encoding of the circuit using lists, and the circuit.

Genetic Programming Algorithm
t=0;
$P_t \leftarrow$ initial population
$P_t \leftarrow fitness(P_t)$
while (stopcondition = false) {
    $S \leftarrow selection(P_t)$;
    $C \leftarrow crossover(S)$;
    $M \leftarrow mutation(C)$;
    t=t+1;
    $P_t \leftarrow fitness(M)$;
}

Several issues regarding the application of Genetic Programming as a problem solving tool for Boolean function synthesis are discussed next.

- **Implementation language:** Although the implementation language is not relevant for the results, we chose Prolog because lists are natural structures of this language and allow the representation of trees. The evaluation of either circuit just requires one predicate that translates a list into a tree.
- **Initial population:** In genetic programming, the size of the trees plays an important role in the search. In our work, we adopted the

following setting for the size of the trees which was experimentally derived: maximum tree height should not exceed half the number of variables of the Boolean function. These trees could be required to be complete binary trees but our strategy was to randomly create them as to have a rich phenotypic blend in the population.

- **Representation:** A circuit is represented using binary trees, and trees are encoded as Prolog lists. This representation is less flexible than directed acyclic graphs (used in (Drechsler et. al., 1998)) but still suitable to generate circuits for pass transistor logic. A circuit tree is a recursive list of triplets of the form: $(mux, left-child, right-child)$. Mux is assigned a control variable, and either child could be a subtree or a leaf. The muxes are treated as "active high" elements, therefore the left subtree is followed when the control is 0, and the right subtree otherwise. The tree captures the essence of the circuit topology allowing only the children to feed their parent node, as shown in Figure 2. The representation also captures with no bias the requirement for the leaves of being only 0 or 1.

- **Crossover operator:** The exchange of genetic information between two parent trees is accomplished by exchanging subtrees as shown in Figure 3. Crossover points are randomly selected, therefore, node-node, node-leaf, and leaf-leaf exchanges are allowed since they produce correct circuits. The particular case when the root node is selected to be exchanged with a leaf is disallowed, so that invalid circuits are never generated.

  In Figure 3, two parents exchange genetic information (subtrees circled) and produce two children in the way used in this paper.

- **Mutation operator:** Mutation is a random change with very low probability of any gene of a chromosome. The mutation of a tree can alter a mux or a leaf. If a mux is chosen then a random variable is generated anew and placed as a new gene value. The mutation of a leaf is as simple as the changing of a 0 to 1, and 1 to 0. The mutation of both a node and a leaf of the tree is shown in Figure 4.

- **Fitness function:** The design of the fitness function using entropy principles is explained in Section 7. Nevertheless, every fitness function used in our experiments works in two stages since the goal is twofold: the synthesis of 100% functional circuits, and their minimization. At stage one, genetic programming explores the search space and builds improved solutions over partial solutions until it finds the first 100% functional circuit. The fitness function for this

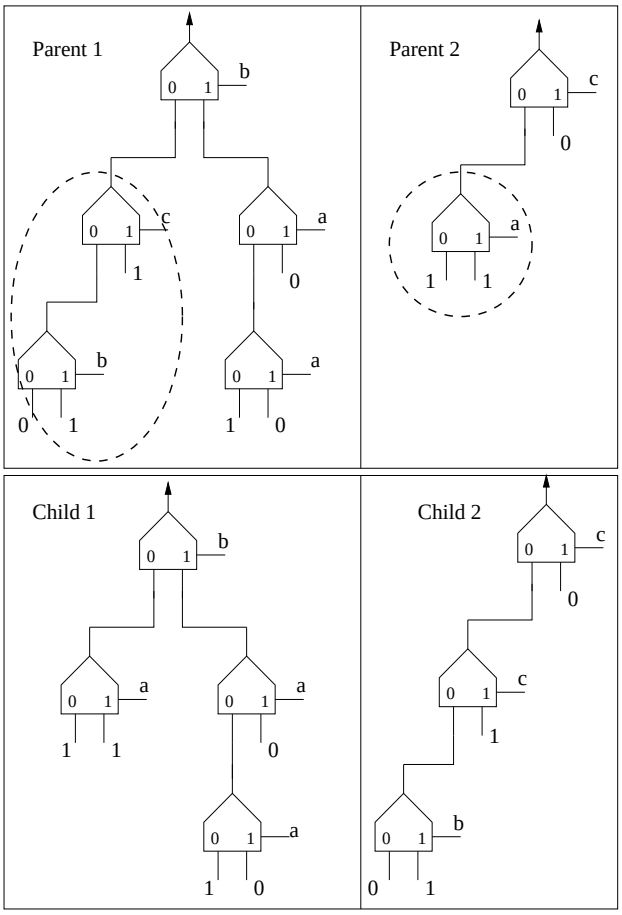

Figure 3. The crossover operator over trees encoding circuits.

stage uses entropy concepts in order to reproduce the truth table. Once the first functional circuit appears in the population, a second fitness function is activated for measuring the fitness of the new circuit. Thus, if a circuit is not 100% functional its fitness value is estimated through entropy; if the circuit is 100% functional its fitness value denotes its size and smaller circuits are preferred over larger ones. The fitness value of a 100% functional circuit is always larger than the value of a non functional one, so that circuits are protected from fitness conflicts.

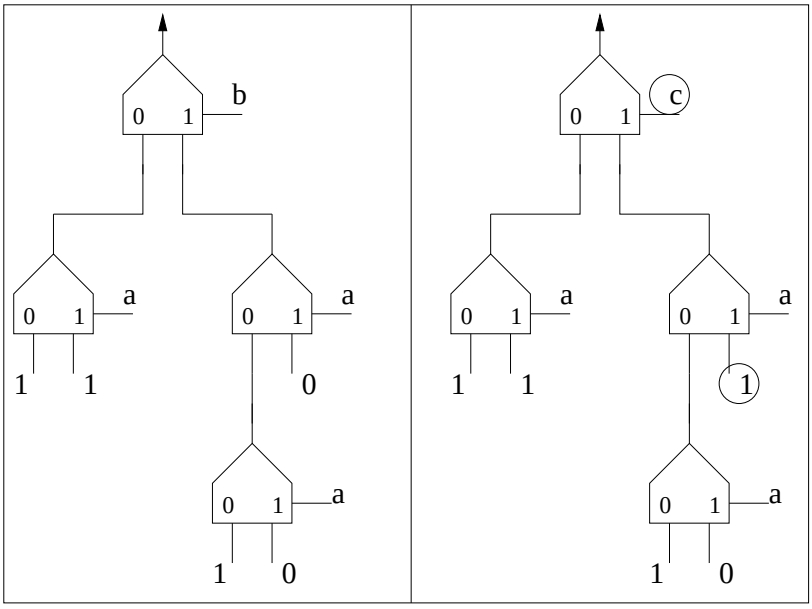

Figure 4. Mutation operation over a tree (two mutations are shown).

7. Entropy and Circuits

Entropy has to be carefully applied to the synthesis of Boolean functions. Let us assume any two Boolean functions, $F1$ and $F2$, and a third $F3$ which is the one's complement of F2, then

$$F3 \neq F2$$

For these complementary functions,

$$H(F2) = H(F3)$$

Also Mutual Information shows a similar behavior.

$$MI(F1, F2) == MI(F1, F3)$$

The implications for Evolutionary Computation are important since careless use of entropy-based measures can nullify the system's convergence. Assume the target Boolean function is T. Then, $MI(T, F2) = MI(T, F3)$, but only one of the circuits implementing $F2$ and $F3$ is close to the solution since their Boolean functions are complementary. A fitness function based on mutual information will reward both circuits with the same value, but one is better than the other. Things could get worse as evolution progresses because the mutual information increases when the circuits are closer to the solution, but in fact, two

complementary circuits are then given larger rewards. The scenario is one in which the population is driven by two equally strong attractors, hence convergence is never reached.

The fitness function of that scenario is as follows. Let us assume T is the target Boolean function (must be seen as a Boolean vector), and C is the output vector of any circuit in the population. Our fitness function is either the maximization of mutual information or the minimization of the conditional entropy term. This is,

$$bad fitness function\#1 = MI(T,C) = H(T) - H(T|C) \qquad (9)$$

The entropy term $H(T)$ is constant since T is the target vector. Therefore, instead of maximizing mutual information, the fitness function can only minimize the conditional entropy,

$$bad fitness function\#2 = H(T|C) \qquad (10)$$

We called *bad* to these entropy-based fitness functions because we were not able to find a solution with them. Although mutual information has been described as the "common" information shared by two random processes, the search space is not amenable for evolutionary computation. In Figure 5 we show this search space over mutual information for all possible combinations with two binary strings of 8 bits. The area shown corresponds to about $\frac{1}{4}$ ($[1,150] \times [1,150]$) of the whole search space of ($[1,254] \times [1,254]$) (the values 0 and 255 were not used). Horizontal axes are decimal values of 8 bit binary strings, and height represents mutual information.

The mutual information space, clearly full of spikes, does not favor the area of common information. For any two equal vectors, their Mutual Information lies on the line at 45^o (over points $\{(1,1),(2,2),(3,3) \ldots (n,n)\}$). In the next Section we continue this discussion and design fitness functions whose *landscape* seems more promising for exploration.

8. Fitness Function based on Normalized Mutual Information

So far we have described the poor scenario where the search is driven by a fitness function based on the sole mutual information. We claim that fitness functions based on Normalized Mutual Information (NMI) should improve the performance of the genetic programming algorithm because of the form of the NMI landscape. This is shown in Figure 6 for two 8-bit vectors (as we did for MI in Section 7, Figure 5). Note on the figure how the search space becomes more regular and, more important yet, note the appearance of the *wall* at 45^o where both strings are equal.

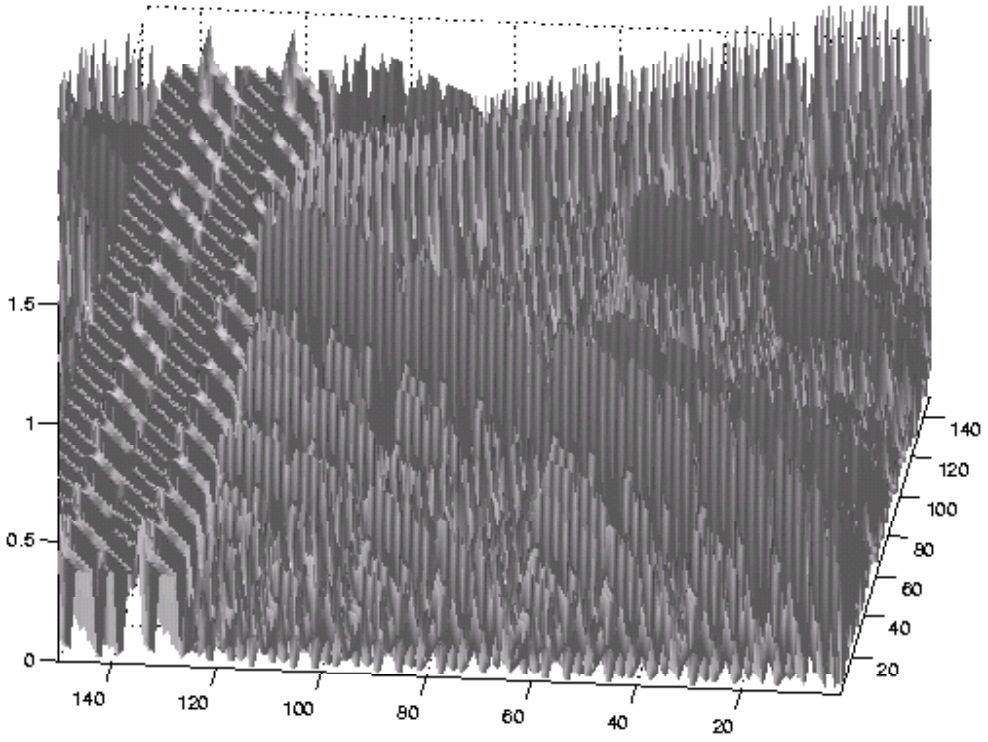

Figure 5. The search space of Mutual Information (Equation 9).

We propose three new fitness functions based on Normalized Mutual Information (Equation 7) and report experiments using the following three fitness functions (higher fitness means better).

Let us assume a target Boolean function of m attributes $T(A_1, A_2, \ldots, A_m)$, and the circuit Boolean function C of the same size. In the following, we propose variations of the basic fitness function of Equation 11, and discuss the intuitive idea of their (expected) behavior.

$$fitness = (Length(T) - Hamming(T, C)) \times NMI(T, C) \qquad (11)$$

We tested Equation 11 in the synthesis of several problems and the results were quite encouraging. Thus, based on this primary equation we designed the following fitness functions. In Figure 7 we show the *fitness landscape* of Equation 11.

$$fitness1 = \sum_{i=1}^{m} \frac{fitness}{NMI(A_i, C)} \qquad (12)$$

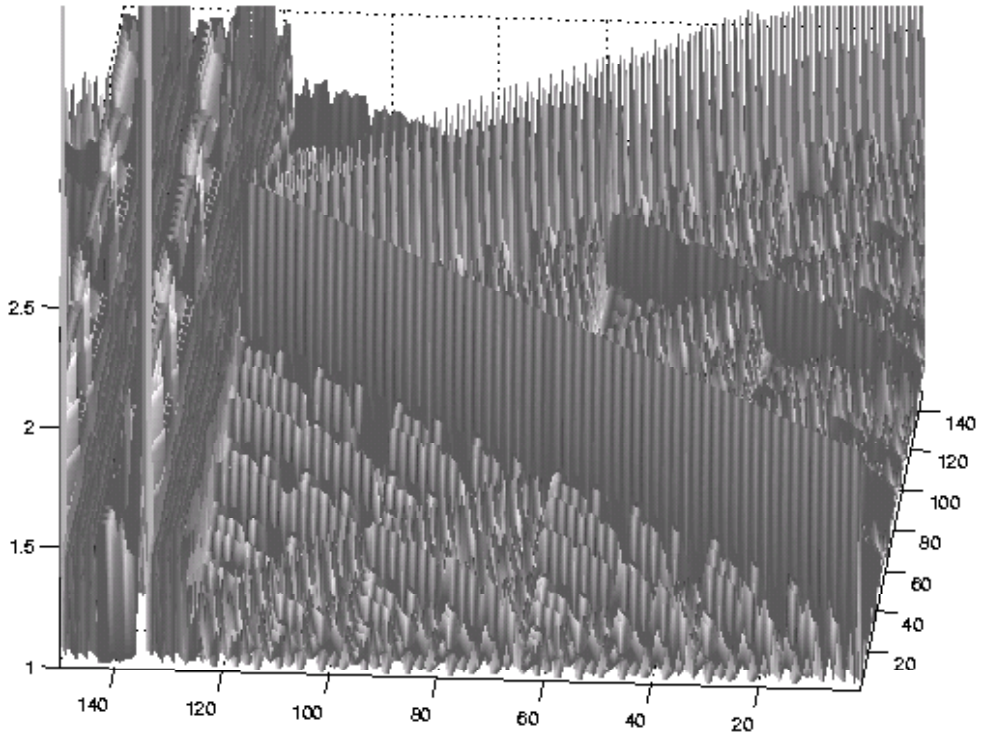

Figure 6. The search space of Normalized Mutual Information (Equation 7).

$$fitness2 = \sum_{i=1}^{m} fitness \times NMI(A_i, C) \tag{13}$$

$$fitness3 = (Length(T) - Hamming(T, C)) \times (10 - H(T|C)) \tag{14}$$

The function fitness, Equation 11, is driven by NMI(T,C) and adjusted by the factor $Length(T) - Hamming(T, C)$. This factor tends to zero when T and C are far in Hamming distance, and tends to $Length(T)$ when T and C are close in Hamming distance. The effect of the term is to give the correct rewarding of NMI to a circuit C close to T. Equation 11 is designed to remove the convergence problems described in the previous section.

$Fitness1$ and $Fitness2$, Equations 12 and 13, combine NMI of T and C with NMI of C and the attributes A_k of the target function. Thus, $fitness1$ and $fitness2$ look for more information available in

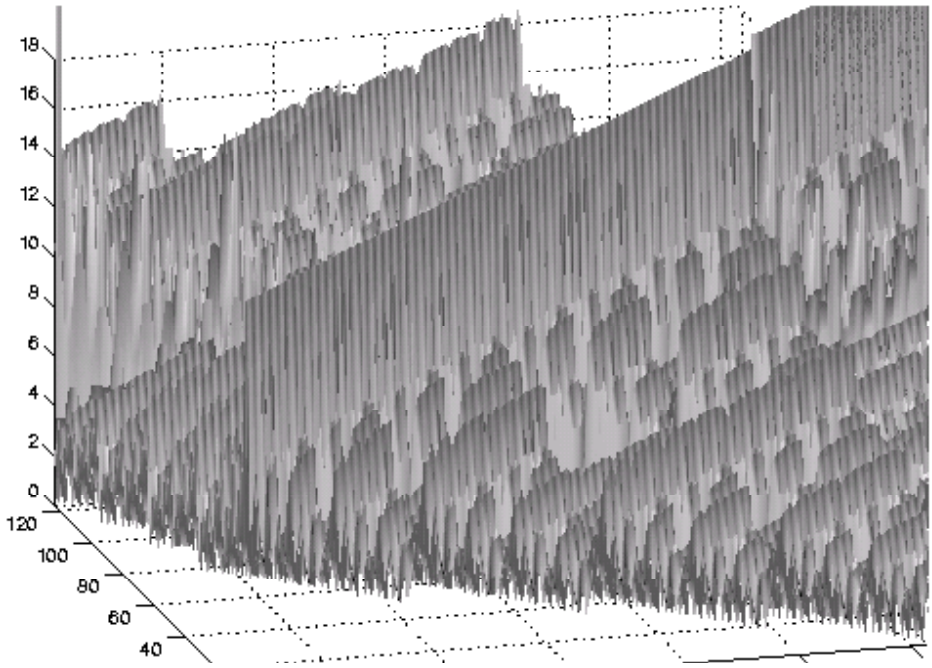

Figure 7. Fitness landscape of: $f = (Length(T) - Hamming(T, C)) \times NMI(T, C)$.

the truth table in order to guide the search. $Fitness3$ is based on conditional entropy and it uses the mentioned factor to suppress the reproduction of undesirable trees. Since conditional entropy has to be minimized we use the factor $10 - H(T|C)$ in order to maximize fitness. Equations 10 and 12 use the conditional entropy term. Nevertheless, only Equation 12 works fine. As a preliminary discussion regarding the design of the fitness function, the noticeable difference is the use of Hamming distance to guide the search towards the aforementioned *optimum wall* of the search space. The Hamming distance favors the destruction of individuals on one side of the wall, and favors the other side. Thus, in principle, there is only one attractor in the search space.

9. Experiments

In the following experiments we find and contrast the convergence of the genetic programming system for the three fitness functions of Equations 12,13,14.

Table II. Generation number where the first 100% functional circuit is found, and the generation where the optimum is found, for our three proposed fitness functions.

Event	Gen. at fitness1	Gen. at fitness2	Gen. at fitness3
100% Functional	13 ± 5	14 ± 7	18 ± 6
Optimum Solution	30 ± 7	30 ± 10	40 ± 20

Table III. Generation number where the first 100% functional circuit is found, and the generation where the optimum is found, for our three proposed fitness functions.

Event	Gen. at fitness1	Gen. at fitness2	Gen. at fitness3
100% Functional	39 ± 12	40 ± 11	50 ± 12
Optimum Solution	160 ± 15	167 ± 15	170 ± 20

9.1. Experiment 1

Here we design the following (simple) Boolean function:

$$F(a,b,c,d) = \sum(0,1,2,3,4,6,8,9,12) = 1$$

We use a population size of 300 individuals, a crossover rate (p_c) of 0.35, a mutation rate (p_m) of 0.65, and a maximum of 100 generations. The optimal solution has 6 nodes, thus we find the generation in which the first 100% functional solution appears, and the generation number where the optimal is found. The problem was solved 20 times for each fitness function. Table II shows the results of these experiments.

9.2. Experiment 2

Our second test function is:

$$F(a,b,c,d,e,f) = ab + cd + ef$$

In this case, we adopted a population size of 600 individuals, $p_c = 0.35$, $p_m = 0.65$, and a maximum of 200 generations. The optimal solution has 14 nodes. Each problem was solved 20 times for each fitness function. Table III shows the results of these experiments.

A solution found to this problem is shown in Figure 8. The evolutionary solution is equivalent to the optimum reported by Reduced Order Binary Decision Diagram techniques.

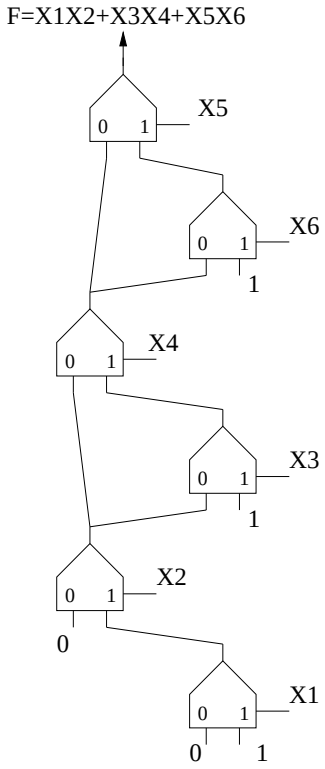

Figure 8. Solution found by Genetic Programming to Experiment 2

9.3. Experiment 3

Our third problem is related to partially specified Boolean functions (Hernández Aguirre et al., 2000). With this experiment we address the ability of the system to design Boolean functions with "large" numbers of arguments and specific topology. For this, we have designed a synthetic problem where the topology is preserved when the number of variables increases.

Boolean functions with $2k$ variables are implemented with $(2*2k)-1$ binary muxes *if* the truth table is specified as shown in Table IV.

We ran experiments for $k = 2, 3, 4$, thus 4,8, and 16 variables and we contrasted these results with the best known so far for this problem (reported in (Hernández Aguirre et al., 2000)). For completeness, all previous results are reported together with the results of the new experiments in Table V, where we use the three fitness functions proposed before (Equations 12,13,14).

All parameters are kept with no changes for similar experiments, average is computed for 20 independent runs. In previous work we used a fitness function based on the sole Hamming distance between

Table IV. Partially specified Function of Example 3 needs $(2*2k)-1$ muxes.

ABCD	F(ABCD)
0 0 0 0	0
0 0 0 1	1
0 0 1 0	1
0 1 0 0	1
1 0 0 0	1
0 1 1 1	1
1 0 1 1	1
1 1 0 1	1
1 1 1 0	1
1 1 1 1	0

Table V. Generation number where the first 100% functional circuit is found, and the generation where the optimum is found, for the three proposed fitness functions.

k	variables	size	Avg(previous)	Avg(fitness1)	Avg(fitness2)	Avg(fitness3)
2	4	7	60	60	60	60
3	8	15	200	190	195	194
4	16	31	700	740	731	748
5	32	63	2000	2150	2138	2150

the current solution of an individual and the target solution of the truth table (Hernández Aguirre et al., 2000). One important difference is the percentage of correct solutions found. Previously, we reported that in 90% of the runs we found the solution (for the case of fitness based on Hamming distance). For the three fitness functions based on entropy we found the solution in 99% of the runs.

9.4. Experiment 4

Our fourth (and last) problem, is the synthesis of even 4-parity circuits (the output of the circuit is 1 if the number of ones assigned to the input variables is odd). This experiment is harder to solve because only XOR gates are used in the optimum solution. Since our approach will need to implement XOR gates by using muxes, or make some abstraction of the overall circuit, interesting behaviors on the fitness functions will be

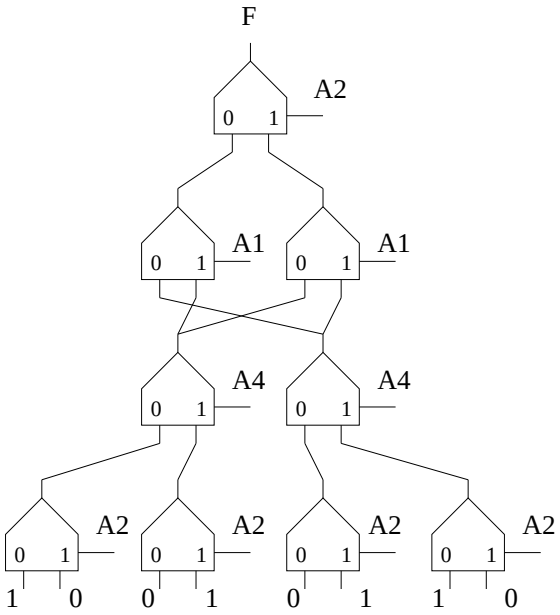

Figure 9. Optimum solution to even 4-parity circuit problem

Table VI. Percentage of optimum solutions found in 30 runs, for our three proposed fitness functions.

Event	Fitness1	Fitness2	Fitness3	Hamming	H-NMI
%Opt. Solutions	54.5%	44.1%	0.0%	36.6%	36.8%

observed. In this case, we adopted a population size of 810 individuals, $p_c = 0.35$, $p_m = 0.65$, and a maximum of 300 generations. Each problem was solved 30 times for each fitness function. The optimal solution has 15 nodes, which after removing similar branches gets its final form shown in Figure 9.

For this experiment we report the number of optimum solutions found as a percentage of trials (30). The results are shown in Table VI

The first three columns are similar to previous experiments, the column labeled "Hamming" indicates the use of a fitness function optimizing Hamming distance, and the column labeled "H-NMI" indicates the use of the fitness function described in Equation 11. Except for function Fitness3, all fitness functions found functional circuits in all cases. It is important to remember that Fitness3 is based on conditional entropy and Hamming distance; the detailed results are: about 50% of the runs strayed from convergence showing an ever increasing number

of nodes. In the other 50%, functional solutions were found but showing an erratic behavior. No circuit with optimum fitness solution was found.

Experiments show that Fitness H-NMI is quite similar to fitness Hamming, but Fitness2 and Fitness1 improve H-NMI and Hamming, most likely due to the normalized mutual information measured between the variables of the target and evolving functions.

10. Final Remarks and Conclusions

We have tested in this paper a fitness function using only conditional entropy for circuit synthesis, with no success at all. We believe this is a clear indication of a fitness function that does not take into account entropy properties. Therefore, the evolutionary algorithm cannot converge because there is more than one attractor in the search space. Figure 5 reveals an amorphous search MI landscape with a quite weak wall at 45^o. The left handside of the wall seems more regular than the right handside. Although it is hard to derive any conclusions from this figure, it is clear that no attractor dominates the area and it could explain the failure of the fitness function based on MI only.

The landscape of Normalized Mutual Information seems less chaotic and more regular. The great advantage of a fitness function designed over NMI is the appearance of the wall at 45^o. It is clear that the wall must appear when the random vectors are equal; as the intersection of the vectors increases so it does the MU. What we have shown in this paper is that, in spite of all the credit given to MI as the "real information" shared between two random processes, the NMI landscape is more suitable for searching than the MI landscape. In the landscape of the fitness function of Figure 7, we can see the wall due to equal vectors is preserved, so we believe it is part of the landscape of three fitness functions using Equation 11.

In the first three experiments, the three fitness functions proposed in this paper worked quite well. All of them found the optimum in most cases, thus they are comparable to other fitness functions based on Hamming distance (Hernández Aguirre et al., 2000). Nonetheless, Experiment 4, which is harder since the optimum solution is implemented by only using XOR gates, tell us a different story. Remember that Fitness1 and Fitness2 are based on NMI, and that their design hypothesis is that some relevant information shared between the Boolean variables of the target function and the target function itself, could be extracted and used to guide the search. This seems to be the case of Experiment 4, since the best results are obtained by fitness functions based on NMI.

A final remark goes to the convergence time and quality of results for Experiment 4 previously reported in the specialized literature. Miller et al. (2000a), solved this problem using a genetic algorithm whose evolution is contained by the matrix representation used (called cartesian genetic programming). They found the optimum in 15% of the runs, each run made 4 million fitness function evaluations. In our case, we only need 240,000 fitness function evaluations, and we get the perfect fitness in 54.5% of the trials. It is not possible to derive firm conclusions from the comparison because the representation and the evolutionary technique of each approach is different, but it is worth to note how our GP based approach needs less computational resources to find perfect fitness circuits. From Tables II and III we can give some advantage to normalized mutual information over simple mutual information because it is less biased. Results from Table V and Table VI could imply that mutual information is able to capture some relationship between the data that the sole Hamming distance cannot convey to the population.

11. Future Work

There are two immediate lines for further research in which we are already working. These are the following:

1. **Use of entropy-based measures to estimate the complexity of a tree:** In the first three experiments of this article, we reported the generation at which the first 100% functional solution was found. We also counted the number of muxes in that first functional solution (not reported here), and also the size of the best tree produced along all the evolutionary process. Comparing the size of trees for fitness functions based and not based on entropy, we found shorter trees when using entropy (NMI to be precise). A detailed analysis is in process in order to explain this behavior. It is quite important because shorter trees usually denote shorter convergence time to the solution. Thus, our hypothesis is that entropy could improve the measure of the complexity of a tree and that it could help to relate tree size with target goal. So far, the experiments show that trees tend to grow but evolution keeps their entropy low and with about the same value. Certainly, many different trees can share the same entropy value, but if this is low then it could mean some trees are replicating a branch with low probability of success. Entropy could also be used to keep diversity high. This is of major importance during the exploration phase of the evolutionary algorithm and, therefore, deserves to be explored in more depth.

2. **Circuits with more than one output:** The generation of common or shared branches is the main issue in this type of circuits. Our initial approach has consisted on measuring the mutual information between the output vectors, and to relate the circuit outputs to the argument vectors of the Boolean function. Our preliminary results are encouraging but more work is still necessary in this direction
